INSTRUCTIONS FOR USE

This Clinical Policy provides assistance in interpreting Oxford benefit plans. Unless otherwise stated, Oxford policies do not apply to Medicare Advantage members. Oxford reserves the right, in its sole discretion, to modify its policies as necessary. This Clinical Policy is provided for informational purposes. It does not constitute medical advice. The term Oxford includes Oxford Health Plans, LLC and all of its subsidiaries as appropriate for these policies.

When deciding coverage, the member specific benefit plan document must be referenced. The terms of the member specific benefit plan document [e.g., Certificate of Coverage (COC), Schedule of Benefits (SOB), and/or Summary Plan Description (SPD)] may differ greatly from the standard benefit plan upon which this Clinical Policy is based. In the event of a conflict, the member specific benefit plan document supersedes this Clinical Policy. All reviewers must first identify member eligibility, any federal or state regulatory requirements, and the member specific benefit plan coverage prior to use of this Clinical Policy. Other Policies may apply.

UnitedHealthcare may also use tools developed by third parties, such as the MCG™ Care Guidelines, to assist us in administering health benefits. The MCG™ Care Guidelines are intended to be used in connection with the independent professional medical judgment of a qualified health care provider and do not constitute the practice of medicine or medical advice.

Special Considerations

1. Precertification is required for services covered under the Member's General benefits package when performed in the office of a participating provider. For Commercial plans, precertification is not required, but is encouraged for out-of-network services performed in the office that are covered under the Member's General benefits package. If precertification is not obtained, Oxford may review for medical necessity after the service is rendered.

2. Precertification with review by a Medical Director or their designee is required.

BENEFIT CONSIDERATIONS

Benefit Plan Document Language
Before using this policy, please check the member specific benefit plan document and any federal or state mandates, if applicable. Some states require benefit coverage for services that UnitedHealthcare considers cosmetic procedures.

Coverage Limitations and Exclusions
The following procedures are excluded from coverage:

- Procedures that correct an anatomical Congenital Anomaly without improving or restoring physiologic function are considered Cosmetic Procedures and therefore excluded from coverage. The fact that a Covered Person may suffer psychological consequences or socially avoidant behavior as a result of an Injury, Sickness or Congenital Anomaly does not classify surgery (or other procedures done to relieve such consequences or behavior) as a reconstructive procedure.
- Any procedure that does not meet the criteria in the Coverage Rationale section below.
- Treatment for spider veins and/or telangiectasias is considered to be cosmetic and therefore excluded from coverage.
- Endovenous ablation (radiofrequency and/or laser) of either reticular or telangiectatic veins is not reconstructive and unproven not medically necessary and therefore excluded from coverage.

Essential Health Benefits for Individual and Small Group
For plan years beginning on or after January 1, 2014, the Affordable Care Act of 2010 (ACA) requires fully insured non-grandfathered individual and small group plans (inside and outside of Exchanges) to provide coverage for ten categories of Essential Health Benefits (“EHBs”). Large group plans (both self-funded and fully insured), and small group ASO plans, are not subject to the requirement to offer coverage for EHBs. However, if such plans choose to provide coverage for benefits which are deemed EHBs, the ACA requires all dollar limits on those benefits to be removed on all Grandfathered and Non-Grandfathered plans. The determination of which benefits constitute EHBs is made on a state by state basis. As such, when using this policy, it is important to refer to the member specific benefit plan document to determine benefit coverage.

COVERAGE RATIONALE

Varicose Vein Ablative and Stripping Procedures
Radiofrequency ablation, endovenous laser ablation, stripping, ligation and excision of the great saphenous vein and small saphenous veins are considered reconstructive medically necessary when ALL of the following criteria are present:

- **Junctional Reflux** (see Definitions section):
  - Ablative therapy for the great or small saphenous veins will be considered reconstructive and therefore proven and medically necessary only if junctional reflux is demonstrated in these veins; or
  - Ablative therapy for accessory veins will be considered reconstructive and proven and medically necessary only if anatomically related persistent junctional reflux is demonstrated after the great or small saphenous veins have been removed or ablated.

- **Member must have one of the following functional impairments:**
  - Skin ulceration; or
  - Documented episode(s) of frank bleeding of the varicose vein due to erosion of/or trauma to the skin; or
  - Documented superficial thrombophlebitis or documented venous stasis dermatitis; or
  - Moderate to severe pain causing functional/physical impairment.

- **Venous Size:**
  - The great saphenous vein must be 5.5mm or greater when measured at the proximal thigh immediately below the sapheno-femoral junction via duplex ultrasonography.
O The small saphenous vein or accessory veins must measure 5 mm or greater in diameter immediately below the appropriate junction.

- **Duration of reflux, in the standing or reverse Trendelenburg position that meets the following parameters:**
  - Greater than or equal to 500 milliseconds (ms) for the great saphenous, small saphenous or principle tributaries
  - Perforating veins > 350 ms
  - Some duplex ultrasound readings will describe this as moderate to severe reflux which will be acceptable.

**Ablation of perforator veins is considered reconstructive and medically necessary when the following criteria are present:**
- Evidence of perforator venous insufficiency measured by recent duplex ultrasonography report (see criteria above); and
- Perforator vein size is 3.5mm or greater; and
- Perforating vein lies beneath a healed or active venous stasis ulcer.

**Endovenous mechanochemical ablation (MOCA) of varicose veins using a percutaneous infusion catheter is unproven and not medically necessary for treating venous reflux.**

There is insufficient evidence in the clinical literature supporting the safety and efficacy of MOCA for treating varicose veins. Further results from large, well-designed studies are needed to support the clinical utility of this approach.

**Ligation Procedures**

**Ligation of the great saphenous vein at the saphenofemoral junction, as a stand-alone procedure, is unproven and not medically necessary for treating venous reflux.**

Ligation performed without stripping or ablation is associated with high long-term recurrence rates due to neovascularization.

**Ligation of the small saphenous vein at the saphenopopliteal junction, as a stand-alone procedure, is unproven and not medically necessary for treating venous reflux.**

Ligation performed without stripping or ablation is associated with high long-term recurrence rates due to neovascularization.

**Ligation at the saphenofemoral junction, as a stand-alone procedure, is proven and medically necessary, when used to prevent the propagation of an active clot to the deep venous system in patients with ascending superficial thrombophlebitis who fail or are intolerant of anticoagulation therapy.**

**Ligation at the saphenofemoral junction, as an adjunct to radiofrequency ablation or endovenous laser ablation of the main saphenous veins, is unproven and not medically necessary for treating venous reflux.**

Published clinical evidence has not demonstrated that the addition of saphenofemoral ligation to endovenous ablation procedures provides an additive benefit in resolving venous reflux or preventing varicose vein recurrence. Endovenous ablation is a clinically effective therapy for treating venous reflux. Adding ligation to the procedure adds clinical risk without adding clinical benefit.

**DEFINITIONS**

When applicable, please refer to the member specific benefit plan document for definitions.

**Accessory/Tributary Vein:** Axial accessory or tributary saphenous veins indicate any venous segment ascending parallel to the great saphenous vein and located more superficially above the saphenous fascia, both in the leg and in the thigh. These can include the anterior accessory vein, the postero-medial vein, circumflex veins [anterior or posterior], intersaphenous veins, Giacomini vein or posterior [Leonardo] or anterior arch veins.

**Congenital Anomaly:** A physical developmental defect that is present at the time of birth, and that is identified within the first twelve months of birth.

**Cosmetic Procedures:** Procedures or services that change or improve appearance without significantly improving physiological function, as determined by UnitedHealthcare.

**Duplex Ultrasonography:** Combines a real-time B mode scanner with built-in Doppler capability. The B mode scanner outlines anatomical structure while Doppler detects the flow, direction of flow and flow velocity.

**Duplicate Saphenous Vein:** True duplication of a saphenous vein is rare. The saphenous veins are found in the saphenous canal or fascial envelope, which is bounded by the superficial and deep fascia. A true dual system occurs
when both veins are found inside the saphenous canal. A second vein that runs parallel to the saphenous vein, but outside the saphenous canal, is considered an accessory vein (Cronenwett and Johnston, 2014).

**Endovenous Ablation:** A minimally invasive procedure that uses heat generated by radiofrequency (RF) or laser energy to seal off damaged veins.

**Functional/Physical Impairment:** A physical/functional or physiological impairment causes deviation from the normal function of a tissue or organ. This results in a significantly limited, impaired, or delayed capacity to move, coordinate actions, or perform physical activities and is exhibited by difficulties in one or more of the following areas: physical and motor tasks; independent movement; performing basic life functions.

**Great Saphenous Vein:** The GSV originates from the dorsal arch of the foot and progresses medially and proximally along the distal extremity to join the common femoral vein.

**High Quality Photograph:** Ideally, a high-quality print should be in color have at least 200 pixels per inch. It must be detailed enough to show the patient’s anatomy that is described in the physician’s office notes If submitted as a hard copy, the image must be on photographic paper.

**Junctional Reflux:** Reflux that exceeds a duration of 0.5 seconds at either:
- The saphenofemoral junction (SFJ) - confluence of the great saphenous vein and the femoral vein; or
- The saphenopopliteal junction (SPJ) - confluence of the small saphenous vein and the popliteal vein

**Ligation:** Tying off a vein.

**Reconstructive Procedures:** Reconstructive procedures when the primary purpose of the procedure is either to treat a medical condition or to improve or restore physiologic function. Reconstructive procedures include surgery or other procedures which are associated with an Injury, Sickness or Congenital Anomaly. The primary result of the procedure is not a changed or improved physical appearance.

Procedures that correct an anatomical Congenital Anomaly without improving or restoring physiologic function are considered Cosmetic Procedures. The fact that a Covered Person may suffer psychological consequences or socially avoidant behavior as a result of an Injury, Sickness or Congenital Anomaly does not classify surgery (or other procedures done to relieve such consequences or behavior) as a reconstructive procedure.

**Reticular Vein:** Reticular veins are dilated dermal veins less than 4mm in diameter that communicate with either or both telangiectasia and saphenous tributaries.

**Sickness:** Physical illness, disease or Pregnancy. The term Sickness as used in this *Certificate* does not include mental illness or substance abuse, regardless of the cause or origin of the mental illness or substance abuse.

**Small Saphenous Vein:** Superficial vein of the calf.

**Spectral Doppler Flow Imaging:**
- Examines flow at one site
- Provides a detailed analysis of distribution of flow
- Provides good temporal resolution, capable of examining flow waveform
- Allows for calculation of velocity and indices

**Spider Vein:** Spider Veins/Telangiectasia are the permanent dilation of preexisting small blood vessels, generally up to 1mm in size.

**Stripping:** Surgical removal of superficial veins

**Superficial Thrombophlebitis:** Inflammation of a vein due to a blood clot in a vein just below the skin’s surface.

**Telangiectasia:** See *Spider Vein*.

**Varicose Veins:** Abnormally enlarged veins that are frequently visible under the surface of the skin; often appear blue, bulging and twisted.

**Venous Reflux/Insufficiency:** Venous reflux is reversed blood flow in the veins [away from the heart]. Abnormal [pathological reflux] is defined as reverse flow that lasts beyond a specified period of time as measured by Doppler ultrasound. Normal [physiological reflux] is defined as reverse flow that lasts less than a specified period of time as
measured by Doppler ultrasound. Abnormal [pathological reflux] times exceed different thresholds depending on the system of veins:

- Deep veins: 1 sec
- Superficial veins: 0.5 sec
- Perforator veins: 0.35 sec

**Venous Stasis Dermatitis**: A skin inflammation due to the chronic buildup of fluid (swelling) under the skin.

**APPLICABLE CODES**

The following list(s) of procedure and/or diagnosis codes is provided for reference purposes only and may not be all inclusive. Listing of a code in this policy does not imply that the service described by the code is a covered or non-covered health service. Benefit coverage for health services is determined by the member specific benefit plan document and applicable laws that may require coverage for a specific service. The inclusion of a code does not imply any right to reimbursement or guarantee claim payment. Other Policies may apply.

**Coding Clarification**: According to the American Medical Association (AMA), CPT code 37241 is specific to venous embolization/occlusion and excludes lower extremity venous incompetency. Coding instructions state that 37241 should not be used to report treatment of incompetent extremity veins. For sclerosis of veins or endovenous ablation of incompetent extremity veins, see 36468-36479 (CPT Assistant, 2014).

**DESCRIPTION OF SERVICES**

Varicose veins are enlarged veins that are swollen and raised above the surface of the skin. They can be dark purple or blue, and look twisted and bulging. Varicose veins are commonly found on the backs of the calves or on the inside of the leg. Veins have one-way valves that help keep blood flowing towards the heart. When the valves become weak or damaged and do not close properly, blood can back up and pool in the veins causing them to get larger. The resulting condition is known as venous insufficiency or venous reflux. Varicose veins may lead to complications such as pain, blood clots or skin ulcers.

Varicose veins are treated with lifestyle changes and medical procedures done either to remove the veins or to close them. Endovenous ablation therapy uses lasers or radiofrequency energy to create heat to close off a varicose vein.

©1996-2017, Oxford Health Plans, LLC
Vein stripping and ligation involves tying shut and removing the veins through small cuts in the skin (National Heart, Lung and Blood Institute, 2014).

Endomechanical ablation uses a specialized, rotating catheter (e.g., ClariVein) to close off a varicose vein by damaging the vessel lining prior to injecting a sclerosing agent. This technique is also referred to as mechanochemical ablation (MOCA), mechanico-chemical endovenous ablation (MCEA) and mechanically enhanced endovenous chemical ablation (MEECA).

**CLINICAL EVIDENCE**

Also see References section below.

Boersma et al. (2016) performed a systematic review and meta-analysis of treatment modalities for small saphenous vein insufficiency. The review included 49 studies (5 randomized controlled trials, 44 cohort studies) reporting on the different treatment modalities: surgery (n=9), endovenous laser ablation (EVLA) (n=28), radiofrequency ablation (RFA) (n=9), ultrasound-guided foam sclerotherapy (UGFS) (n=6) and MOCA (n=1). The primary outcome of anatomical success was defined as closure of the treated vein on follow-up duplex ultrasound imaging. Secondary outcomes were technical success and major complications. The pooled anatomical success rate was 58.0% for surgery in 798 veins, 98.5% for EVLA in 2950 veins, 97.1% for RFA in 386 veins and 63.6% for UGFS in 494 veins. One study reported results of MOCA, with an anatomical success rate of 94%. Neurologic complications were most frequently reported after surgery and thermal ablation. Deep venous thrombosis was a rare complication. The authors concluded that EVLA and RFA are preferred to surgery and foam sclerotherapy in the treatment of small saphenous vein insufficiency. Although data on nonthermal techniques is still sparse, the potential benefits, especially the reduced risk of nerve injury, might be of considerable clinical importance.

O'Hare et al. (2008) conducted a multicenter, prospective cohort study of patients undergoing small saphenous vein surgery (SSV). Patients were evaluated at six weeks and one year after surgery. A total of 204 legs were reviewed at one year; 67 had small saphenous varicose vein stripping, 116 had saphenopopliteal junction (SPJ) disconnection only and the remainder had miscellaneous procedures. The incidence of visible recurrent varicosities at one year was lower after SSV stripping than after disconnection only, although this did not reach statistical significance. The rate of SPJ incompetence detected by duplex at one year was significantly lower in patients who underwent SSV stripping than in those who did not.

In a 5-year follow-up from two randomized controlled trials, Rass et al. (2015) compared the long-term clinical efficacy of endovenous laser ablation (EVLA) with high ligation and stripping (HLS) as standard treatment for great saphenous vein (GSV) incompetence. Two hundred and eighty one legs (81% of the study population) were evaluated with a median follow up of 60.4 (EVLA) and 60.7 months (HLS). Overall, REVAS was similarly observed in both groups: 45% (EVLA) and 54% (HLS), p = .152. Patients of the EVLA group showed significantly more clinical recurrences in the operated region (REVAS: same site): 18% vs. 5%, p = .002. In contrast, an increase in different site recurrences was observed in the HLS group: 50% vs. 31%, p = .002. Duplex detected saphenofemoral refluxes occurred more frequently after EVLA: 28% vs. 5%, p < .001. Both treatments improved disease severity and quality of life without any difference. The authors concluded that EVLA and HLS are comparably effective concerning overall REVAS, improvement of disease severity, and quality of life. In terms of same site clinical recurrence and saphenofemoral refluxes, HLS is superior to EVLA 5 years after treatment.

Gauw et al. (2016) evaluated 5-year outcomes from a randomized, controlled trial to compare the long-term results (groin-related recurrence, great saphenous vein [GSV] occlusion rate, clinical class, etiology, anatomy, and pathophysiology [CEAP] staging, and quality of life [QoL]) after the treatment of a GSV incompetence by saphenofemoral ligation and stripping (SFL/S) with endovenous laser ablation bare fiber, 980 nm (EVLA). Patients (n=121; 130 legs) with GSV insufficiency and varicose veins were randomized to either undergo SFL/S or EVLA. At the 5-year follow-up, a significantly higher varicose vein recurrence rate originated at the SFJ region after EVLA compared with SFL/S. There were no differences in the relief of venous symptoms, CEAP staging, or general QoL between the groups.

In a multicenter, randomized controlled trial with up to 6 years follow-up, Flessenkämper et al. (2016) compared high ligation and stripping to endovenous laser ablation for the therapy of great saphenous vein varicosity. Patients (n=449 were randomized into three different treatment groups: high ligation and stripping group (n = 159), endovenous laser ablation group (n = 142; 980 nm, 30 W continuous mode, bare fiber) or a combination of laser ablation with high ligation (endovenous laser ablation group/ high ligation group, n = 148). The authors observed that clinical recurrence appears with the same frequency in all three treatment groups, but the responsible pathological mechanisms seem to differ. Most reflux into the great saphenous vein and side branches appears after endovenous laser ablation, whereas more saphenofemoral junction-independent recurrences are seen after high ligation/stripping.
In a literature review of long-term results following high ligation supplemented by sclerotherapy, Recek (2004) found that ligation of the saphenofemoral junction alone provokes a higher recurrence rate in comparison with high ligation and stripping. The hemodynamic improvement achieved immediately after high ligation deteriorates progressively during the follow-up owing to recurrent reflux.

Woźniak et al. (2016) conducted a quantitative-qualitative analysis of complications and failure of endovenous laser ablation (EVLA) and radiofrequency ablation (RFA) in a 5-year follow-up. One hundred ten adult participants with varicose veins clinical grade C2 to C6, treated for isolated great saphenous vein (GSV) or small saphenous vein (SSV) insufficiency in a single lower extremity in 2009 to 2010, were enrolled and subdivided into EVLA (n = 56) and RFA (n = 54) groups. Both groups were compared for demographics, disease stage, affected veins, perioperative, and postoperative complications as well as treatment efficacy. The perioperative and postoperative complications were statistically insignificant. Treatment efficacy, expressed as the number of participants with recurrent varicosity and recanalization, was comparable in both groups. The clinically significant recanalization rate was 3.6% and 5.6% in EVLA and RFA groups, respectively. The authors concluded that EVLA and RFA for the management of lower extremity varicose vein offer comparable efficacy and safety in a 5-year follow-up.

In a systematic review and meta-analysis of randomized controls of endovenous ablation (EVA) of the great saphenous vein (GSV), O’Donnell et al. (2016) evaluated recurrence and cause of varicose veins after surgery (REVAS). Seven RCTs provided eight comparisons (one study compared both types of EVA to a comparator arm): three used radiofrequency ablation, and five employed endovenous laser ablation. Overall recurrent varicose veins developed in 125 limbs after EVA (22%), with no difference in the incidence vs the ligation and stripping (L&S) group (22%) based on the number of limbs available at the time of the development of recurrence for both groups, but this incidence is dependent on the length of follow-up after the initial treatment. Neovascularization occurred in only two limbs (2%) after EVA vs 18 (18%) in the L&S group. Recanalization was the most common cause of REVAS for EVA (32%; 40 of 125 limbs), followed by the development of anterior accessory saphenous vein incompetence (19%; 23 of 125 limbs). The authors concluded that there is no difference in the incidence of REVAS for EVA vs L&S, but the causes of REVAS are different with L&S.

Wichers et al. (2005) performed a systematic review of randomized trials evaluating the safety and efficacy of medical (anticoagulants) or surgical (ligation or stripping of the affected veins) treatments of superficial vein thrombosis (SVT) for the prevention of deep vein thrombosis (DVT) and pulmonary embolism (PE). Five studies were included. Pooling of the data was not possible due to the heterogeneity among the studies. Three studies had major methodological drawbacks limiting the clinical applicability of the results. One of the remaining (pilot) studies showed a non-significant trend in favor of high-compared to low-dose unfractionated heparin for the prevention of venous thromboembolism (VTE). The last remaining study showed a non-significant trend in favor of short-term treatment with low-molecular-weight heparin (LMWH) or a non-steroidal anti-inflammatory drug (NSAID) as compared to placebo shortly after treatment with respect to VTE, but the apparent benefit disappeared after three months of follow-up. More randomized controlled trials are needed before any evidence-based recommendations on the treatment of SVT for the prevention of VTE can be given. With the lack of solid evidence, the authors suggest treating patients with at least intermediate doses of LMWH. Surgical treatment of SVT may be considered when varicose veins are involved.

Sullivan et al. (2001) performed a systematic review of the literature evaluating surgical and medical management of above-knee superficial thrombophlebitis (AK-STP) not involving the deep venous system. Six studies were included for a total of 246 patients in the surgical arm and 88 patients in the medical arm. Surgical treatment modalities halt the progression of thrombus into the deep venous system through the saphenofemoral junction and reduce the incidence of PE. The two types of surgical treatment were ligation of the great saphenous vein at the saphenofemoral junction or ligation in combination with stripping of the phlebitic vein. Medical therapy consisted of initial intravenous heparin followed by warfarin therapy for a duration varying between 6 weeks and 6 months. The authors offered no definitive conclusions due to reporting of varied outcomes, different follow-up criteria and the retrospective nature of the studies. The differences between the surgical and medical groups were small. The review concludes that medical management with anticoagulants is superior for minimizing complications and preventing subsequent deep vein thrombosis and pulmonary embolism development as compared to surgical treatment with ligation of the great saphenous vein at the saphenofemoral junction or ligation and stripping.

Winterborn et al. (2004) conducted an 11 year follow-up study on the Jones et al. patient group. A cumulative total of 83 legs had developed clinically recurrent varicose veins by 11 years (62%). There was no statistically significant difference between the ligation-only and the stripping groups. Reoperation was required for 20 of 69 legs that underwent ligation alone compared with 7 of 64 legs that had additional long saphenous vein stripping. Freedom from reoperation at 11 years was 70% after ligation, compared with 86% after stripping. The presence of neovascularization, an incompetent superficial vessel in the thigh or an incompetent saphenofemoral junction on duplex imaging at 2 years postoperatively increased the risk of a patient’s developing clinically recurrent veins. Results from the study indicate that stripping the long saphenous vein is recommended as part of routine varicose
vein surgery as it reduces the risk of reoperation after 11 years, although it did not reduce the rate of visible recurrent veins.

Dwerryhouse et al. (1999) designed as a 5-year follow-up study on the Jones et al. patient group. 78 patients (110 legs) underwent clinical review and duplex scan imaging. Sixty-five patients remained pleased with the results of their surgery (35 of 39 stripped vs. 30 of 39 ligated). Reoperation for recurrence was necessary for three of 52 of the legs that underwent stripping vs. 12 of 58 ligated legs. Neovascularization at the saphenofemoral junction was responsible for 10 of 12 recurrent veins that underwent reoperation and also was the cause of recurrent saphenofemoral incompetence in 12 of 52 stripped veins vs. 30 of 58 ligated legs. The authors concluded that stripping reduced the risk of reoperation by two thirds after 5 years and should be routine for primary long saphenous varicose veins.

Jones et al. (1996) conducted a randomized controlled trial of one hundred patients (133 legs) to determine whether routine stripping of the long saphenous vein reduced recurrence after varicose vein surgery. A two year follow-up in 81 patients (113 legs) showed that 89% of patients remained satisfied with the results of their surgery, though 35% had recurrent veins on clinical examination. Recurrence was reduced in patients who had their long saphenous vein stripped. Neovascularization was detected in 52% of limbs and was the most common cause of recurrence.

Rutgers et al. (1994) conducted a prospective randomized study comparing stripping and local avulsions with high ligation of the saphenofemoral junction combined with sclerotherapy for the treatment of great saphenous vein insufficiency. Of 156 consecutive patients, 89 legs were randomly allocated to stripping and 92 to high ligation. Patients were followed-up at 3 months and 1, 2, and 3 years after treatment. At 3 years, 69 limbs in the stripping group (78%) and 73 limbs in the ligation group (79%) were available to follow-up. The authors found that clinical and Doppler ultrasound evidence of reverse flow in the saphenous vein was significantly less after stripping.

Eighty-nine legs with long saphenous vein (LSV) reflux and saphenofemoral junction incompetence were treated by saphenofemoral ligation and multiple avulsions. Patients were randomized to undergo additional stripping of the LSV (n = 43) or no additional treatment (n = 46). At a median of 21 months after surgery, more patients were free of recurrence when the LSV had been stripped compared with saphenofemoral ligation alone. The authors concluded that the addition of LSV stripping to saphenofemoral ligation and multiple avulsions results in a better overall outcome (Sarin et al., 1994).

During endovenous ablation procedures, radiofrequency or laser energy is applied to heat the vein, causing the vessel to close and eventually be absorbed by the body. This technique achieves the same effect as saphenofemoral or saphenopopliteal ligation and stripping. Adding ligation of the main trunk to the procedure has not been shown to provide an additive benefit in resolving venous reflux or preventing varicose vein recurrence.

In a systematic review, Darwood and Gough (2009) found that adjunctive saphenofemoral ligation is not necessary to achieve success with endovenous laser therapy of the great saphenous vein. Similarly, a randomized controlled trial conducted by Desselhoff et al. (2008) found that the addition of saphenofemoral ligation to endovenous ablation made no difference to the short-term outcome of varicose vein treatment. Long-term follow-up at 5 years found similar results (Desselhoff et al. 2011). Further studies with larger patient populations are needed to establish the superiority of adjunctive saphenofemoral ligation in improving long-term outcomes.

Theivacumar et al. (2007) also found that saphenofemoral ligation following endovenous laser ablation was unnecessary. Persistent non-refluxing great saphenous vein tributaries at the saphenofemoral junction did not have an adverse impact on clinical outcome 1 year after successful endovenous laser ablation of the great saphenous vein.

**Endovenous Mechanochemical Ablation**

A Hayes technology assessment concluded that endovenous mechanochemical ablation (MOCA), with the ClariVein system, for the treatment of symptomatic varicose veins appears to be safe and efficacious; however, the overall quality of the evidence is low. The procedure results in a high rate of vessel occlusion over the short term (~90%), and patient satisfaction is high. Validated measures demonstrated improvement in venous disease after the intervention, and adverse effects were minimal. Despite the consistent findings across the studies, most of the studies were small in size, lacked randomization and/or controls and all lacked sufficient follow-up time to determine if any positive effects of MOCA are durable. Several studies were performed by the same experienced group so the generalizability of their findings is unclear. Most studies were supported by the device manufacturer. None of the studies had long-term follow-up, although ongoing studies are expected to yield data on long-term outcomes. No definitive conclusions can be reached regarding the safety and efficacy of MOCA with the ClariVein system until additional evidence from well-designed studies is available, and patient selection criteria have been established (Hayes, 2015).

Witte et al. (2016) reported midterm results of MOCA for treating great saphenous vein (GSV) insufficiency. In a 1-year period, 85 consecutive patients undergoing MOCA with polidocanol in 104 limbs were enrolled in a prospective
In a prospective cohort study, Boersma et al. (2013) evaluated the feasibility, safety and perceived an improved change in health status and an improved disease than patients treated with RFA during the first 14 days after treatment. The lower postoperative pain score was radiofrequency ablation (RFA) and MOCA for great saphenous vein (GSV) incompetence. Sixty patients randomized to mechanochemical ablation (n=60) or radiofrequency ablation (n=59). Maximum pain score was also significantly lower in the mechanochemical ablation group compared to the radiofrequency ablation group. Average pain score was also significantly lower in the mechanochemical ablation group compared to the radiofrequency ablation group. Sixty-six percent attended follow-up at one month, and the complete or proximal occlusion rates were 92% for both groups. At one month, the clinical and quality of life scores for both groups had similar improvements. The long-term data including occlusion rates at six months and quality of life scores are being collected.

Bishawi at al. (2014) conducted a prospective observational multicenter study on the efficacy of MOCA in patients with lower extremity chronic venous disease. A total of 126 patients were included at baseline, 81% females. The mean diameter of the great saphenous vein in the upper thigh was 7.3 mm and the mean treatment length was 38 cm. Adjunctive treatment was performed in 11% of patients during the procedure. Closure rates were 100% at one week, 98% at three months and 94% at six months. Post-procedure complications included hematoma, ecchymosis and thrombophlebitis. There were no cases of venous thromboembolism. The authors concluded that MOCA of the saphenous veins has the advantage of endovenous ablation without tumescent anesthesia. This study is limited by lack of randomization and control and short-term follow-up.

Vun et al. (2015) assessed the efficacy of the ClariVein system for the treatment of superficial vein incompetence. Fifty-one great saphenous veins and six small saphenous veins were treated. Duplex showed a technical success rate of 91%. Comparison with 50 RFA and 40 EVLA procedures showed procedure times were significantly less for ClariVein than for either RFA or EVLA. Median pain scores were significantly lower for ClariVein than for RFA and EVLA. No major complications or deep vein thromboses were reported. Study limitations included small sample size, lack of randomization and control and short-term follow-up. Further data on long-term clinical outcomes is needed.

In a prospective comparison study, van Eekeren et al. (2013) evaluated postoperative pain and quality of life after radiofrequency ablation (RFA) and MOCA for great saphenous vein (GSV) incompetence. Sixty-eight patients with unilateral GSV incompetence were included. Patients treated with MOCA reported significantly less postoperative pain than patients treated with RFA during the first 14 days after treatment. The lower postoperative pain score was associated with a significantly earlier return to normal activities and work. At 6 weeks, patients in both groups perceived an improved change in health status and an improved disease-specific quality of life. This study is limited by lack of randomization and control, small sample size and short-term follow-up.

In a prospective cohort study, Boersma et al. (2013) evaluated the feasibility, safety and 1-year results of MOCA of small saphenous vein (SSV) insufficiency. Fifty consecutive patients were treated using the ClariVein device and...
polidocanol. At the 6-week assessment, all treated veins were occluded. One-year follow-up showed a 94% anatomic success rate and no major complications. The authors concluded that MOCA is a safe, feasible and efficacious technique for treating SSV insufficiency. This study is limited by lack of randomization and control, small sample size and short-term follow-up.

Elias and Raines (2012) assessed the safety and efficacy of the ClariVein® system for mechanochemical ablation of the great saphenous vein (GSV). Thirty GSVs in 29 patients were treated. At six-month follow-up, the primary closure rate was 96.7% with no adverse events reported. The authors concluded that mechanochemical ablation appears to be safe and efficacious. This study is limited by lack of randomization and control, small sample size and short-term follow-up.

In a pilot study, Van Eekeren et al. (2011) evaluated the feasibility and safety of endovenous MOCA for the treatment of great saphenous vein (GSV) incompetence. Thirty limbs in 25 patients (18 women; mean age 52 years) with GSV incompetence were treated with the ClariVein® device. Initial technical success, complications, patient satisfaction and classification by venous clinical severity score (VCSS) were assessed 6 weeks after the treatment. Initial technical success of MOCA was 100%. There were no major adverse events. Duplex ultrasonography at 6 weeks showed 26 (87%) of 30 veins were completely occluded. Three veins showed partial recanalization in the proximal and distal GSV. One patient had full segment recanalization and was successfully retreated. The VCSS significantly improved at 6 weeks. Patient satisfaction was high, with a median satisfaction of 8.8 on a 0-10 scale. The authors concluded that endovenous MOCA is feasible and safe in the treatment of GSV incompetence. Larger studies with a prolonged follow-up are indicated to prove the efficacy of this technique.

In an updated guideline on endovenous mechanochemical ablation for varicose veins, the National Institute for Health and Care Excellence (NICE) (2016) states that current evidence on the safety and efficacy of endovenous mechanochemical ablation for varicose veins appears adequate to support the use of this procedure provided that standard arrangements are in place for consent, audit and clinical governance. Clinicians are encouraged to collect longer-term follow-up data. Clinical trials comparing MOCA to radiofrequency ablation for the treatment of great and small saphenous vein insufficiency are ongoing (Boersma et al., 2014a; van Eekeren et al., 2014b).

**Professional Societies**

**Society for Vascular Surgery (SVS)/American Venous Forum (AVF)**

The SVS and AVF released joint clinical practice guidelines regarding the care of patients with varicose veins (Glovinczki et al., 2011). The guidelines state that endovenous thermal ablation is recommended over high ligation and inversion stripping of the saphenous vein to the level of the knee. Foam sclerotherapy is an option for the treatment of the incompetent saphenous vein. The guidelines do not discuss MOCA. The policy also states that patients who undergo high ligation alone of the great saphenous vein (GSV) have recurrent reflux in the residual GSV. This causes new symptoms and increases the risk of reoperation.

**American College of Phlebology**

The American College of Phlebology Guidelines Committee (Gibson et al., 2016) performed a systematic review of the literature regarding the clinical impact and treatment of incompetent accessory saphenous veins. They developed a consensus opinion that patients with symptomatic incompetence of the accessory great saphenous veins (anterior and posterior accessory saphenous veins) be treated with endovenous thermal ablation (laser or radiofrequency) or ultrasound-guided foam sclerotherapy to eliminate symptomatology (Recommendation Grade 1C).

The American College of Phlebology Guidelines Committee (2014) created a white paper to summarize the evidence-based recommendations in the Glovinczki et al. guidelines (2011) as well as many other current studies. They recommend that named veins (great saphenous vein [GSV], small saphenous vein [SSV], anterior accessory of the great saphenous vein [AAGSV], posterior accessory of the great saphenous vein [PAGSV], intersaphenous vein [Vein of Giacomini]) must have a reflux time > 500 msec regardless of the reported vein diameter (Grade 1A).

Endovenous thermal ablation (laser and radiofrequency) is the Committee’s preferred treatment for saphenous and accessory saphenous (GSV, SSV, AAGSV, PAGSV) vein incompetence (Grade 1B). They suggest mechanical/chemical ablation may also be used to treat truncal venous reflux (Grade 2B). They further comment that open surgery is appropriate in veins not amenable to endovenous procedures but otherwise is not recommended because of increased pain, convalescent time, and morbidity (Grade 1B).

**U.S. FOOD AND DRUG ADMINISTRATION (FDA)**

Vein ligation surgery is a procedure and therefore not subject to FDA regulation.
The ClariVein® infusion catheter (Vascular Insights) received FDA approval (K071468) on March 20, 2008. The device is designed to introduce physician-specified medicaments into the peripheral vasculature. See the following website for more information: [http://www.accessdata.fda.gov/cdrh_docs/pdf7/K071468.pdf](http://www.accessdata.fda.gov/cdrh_docs/pdf7/K071468.pdf). (Accessed November 29, 2016)
